Abstract

The Internet has become a critical communication infrastructure for citizens to organize protests and express dissatisfaction with their governments. This fact has not gone unnoticed, with governments clamping down on this medium via censorship, and circumvention researchers working to stay one step ahead.

In this paper, we explore a promising new avenue for covert channels: real-time strategy video games. Video games have two key features that make them attractive cover protocols for censorship circumvention. First, due to the popularity of gaming platforms such as Steam, there are a lot of different video games, each with their own protocols and server infrastructure. Users of video-game-based censorship-circumvention tools can therefore diversify across many games, making it difficult for the censor to respond by simply blocking a single cover protocol. Second, games in the same genre have many common features and concepts. As a result, the same covert channel framework can be easily adapted to work with many different games. This means that circumvention tool developers can stay ahead of the censor by creating a diverse set of tools and by quickly adapting to blockades created by the censor.

We demonstrate the feasibility of this approach by implementing our coding scheme over two real-time strategy games (including a very popular closed-source game). We evaluate the security of our system prototype – Castle – by quantifying its resilience to a censor-adversary, its similarity to real game traffic, and its ability to avoid common pitfalls in covert channel design. We use our prototype to demonstrate that our approach can provide throughput which is amenable to transfer of textual data, such as e-mail, SMS messages, and tweets, which are commonly used to organize political actions.

1. Introduction

The Internet has become a critical communication infrastructure for citizens to obtain accurate information, organize political actions [1], and express dissatisfaction with their governments [2]. This fact has not gone unnoticed, with governments clamping down on this medium via censorship [3–5], surveillance [6] and even large-scale Internet take downs [7–9]. The situation is only getting worse, with Freedom House reporting 36 of the 65 countries they survey experiencing decreasing levels of Internet freedom between 2013 and 2014 [10].

Researchers have responded by proposing several look-like-something censorship circumvention tools, which aim to disguise covert traffic as another protocol to evade detection by censors. This can take two forms: either mimicking the cover protocol using an independent implementation, as in Skype-Morph [11] and StegoTorus [12], or encoding data for transmission via an off-the-shelf implementation of the cover protocol, as in FreeWave [13].

This has created an arms race between censors and circumvention tools. Many censors now block Tor [14], so Tor has introduced support for “pluggable transports”, i.e. plugins that embed Tor traffic in a cover protocol. There are currently six pluggable transports deployed in the Tor Browser Bundle [15]. Censors have already begun blocking some of these transports [16], and some censors have gone so far as to block entire content-distribution networks that are used by some circumvention systems [17].

Furthermore, recent work has shown that care must be taken when designing and implementing a look-like-something covert channel. For example, Houmansadr et al. showed that, when a covert channel re-implements its cover protocol, the copy is unlikely to be a perfect mimic of the original protocol, and a censor can use the differences to recognize when a client is using the covert channel [18]. However, Geddes et al. demonstrate that even running the cover application is not enough to avoid detection by censors [19] – i.e., approaches like FreeWave may be detected via discrepancies between the application’s regular behavior and its behavior when being used as a covert channel. They classify these discrepancies into three categories: (1) architectural mismatches between communication patterns of the application when it is acting as a covert channel vs. regular operation, (2) channel mismatches between reliability requirements of the application and the covert traffic and (3) content mismatches where the packet contents of the application differ because of the covert traffic being sent in place of regular application traffic.

In light of this state of affairs, this paper argues that video games have several features that make them an attractive target for covert channel development.

There are many games available, enabling circumvention tool developers to create a diverse set of circumvention tools. The number of RTS games has grown rapidly in the last few years, as shown in Figure 1. This growth has been driven in part by the democratization of game publishing, as embodied in game distribution platforms such as Steam [20]. Each game...
uses its own network protocol and infrastructure, so the censor cannot simply block all games using a single rule. Censorship circumvention tools can use this large body of games to avoid a censor’s attempt to block any particular game.

**Video games share common elements, making it possible to use a single framework across many games.** For example, most Real-Time Strategy (RTS) games have the notions of buildings, units, and rally points, and censorship circumvention tools that encode information by interacting with these objects can be easily ported from one RTS game to another. Many games also feature replay logs and similar user interfaces, enabling covert channel frameworks that are only loosely coupled to any particular game.

Circumvention tools can re-use off-the-shelf game implementations to avoid the pitfalls identified by Houmansadr et al. Since games have features that make it relatively easy to automate interaction with the off-the-shelf implementation, circumvention tool developers do not need to re-implement the game (or its network protocol), ensuring that the censorship tool uses a faithful implementation of the game protocol.

**Games provide good architectural, channel, and content matches to censorship circumvention tools for textual communications.** Many game support both peer-to-peer and server-based gaming sessions, so they can adapt to whichever is better for the circumvention tool. Games must maintain synchronized state, so they are loss sensitive, avoiding the pitfalls that Geddes et al. found in FreeWave [13]. Finally, games send frequent small packets, matching textual communications.

**Games have built-in security features that can support secure covert channels.** For example, most games include encryption and authentication to prevent cheating. Many games also support password-protected sessions, which can prevent application-level attacks in which the censor attempts to identify covert channels by joining the game.

By lowering the development cost of creating new covert channels, video games may create an asymmetry that censorship circumvention tools can use to win the arms race against censors. Censors can respond to look-like-something circumvention tools by blocking the cover protocol entirely or attempting to distinguish legitimate uses of the protocol from uses by the covert channel. If developing such blocking tools is time consuming, but the circumvention tool developers can quickly move their tool to a new cover protocol, then there will almost always be effective circumvention tools available for end users.

However, we must answer several questions to understand the feasibility of using video games for covert channels:

- Can video games support good covert channel bandwidth?
- Can we encode data in the video game so that the censor cannot distinguish regular game play from covert channel sessions?
- Can we develop a covert channel framework that can be quickly adapted to new games?

To answer these questions, we have built Castle, a prototype video-game-based covert-channel framework. Castle encodes data as player actions in an RTS game. Castle uses desktop-automation software to execute these actions in the game. The video game software transmits these moves to the other players in the same gaming session, who then decode the message and send replies in the same way.

Castle can be easily adapted to new RTS games. Our current prototype supports two such games: “0-A.D.” [21] and an extremely popular (over three million copies sold) closed-source game that we will refer to as “Aeons” (see Section 8 for details). Castle is easy to port to new RTS games for two reasons.

First, Castle uses only features, such as buildings, units, and “rally points”, that are nearly universal to RTS Games. Thus the high-level architecture and encoding scheme can be re-used across games. Second, Castle is only loosely coupled to game internals. For example, Castle uses desktop-automation software to execute game actions through the game’s standard graphical user interface. Similarly, the Castle decoder reads actions from the game’s replay log, which means that it does not need to understand the game’s network protocol or other internals. For many games, development is made even easier by the ready availability of code to parse their replay logs.

Castle offers good bandwidth for text-based communications. Our current prototype provides between 50 and 200 B/s of bandwidth, depending on configuration parameters. Castle has about 100x more bandwidth than other proposed game-based covert channels [22–24]. With some game-specific tuning, the Aeons version can deliver over 400 B/s. Even 50 B/s is sufficient for email, SMS messages, and tweets, which are widely used organizational tools among political activists. There are also several ways to potentially increase Castle’s bandwidth (see Section 8 for details).

Castle’s design makes it resilient to most classes of attacks. Since Castle uses the underlying game to transmit data, an attacker cannot use simple IP- or port-based blocking to block Castle without blocking the game entirely. When used with games that encrypt and authenticate their traffic, an attacker cannot use deep packet inspection to distinguish Castle traffic from regular game traffic. Encryption and authentication also preclude simple packet injection or manipulation attacks. Since games use network communication to synchronize their state, they are loss sensitive, unlike some VoIP protocols. Thus Castle cannot be distinguished from regular gaming sessions through selective packet delay or dropping attacks. Finally, when used with password-protected gaming sessions, Castle is immune to application-level attacks, such as the censor attempting to join the same gaming session to observe the player’s in-game actions.

We evaluate Castle’s security against statistical traffic-analysis attacks by applying several previously published classifiers. We

---

1Despite the similarity of their names and their common use of video games, Rook and Castle were developed independently and have quite different goals. See Section 8 for details.
find that packet sizes and interpacket times of Castle’s traffic deviate from those of regular human-driven game play by the same amount that different human player’s traffic differ from each other. We also find that the Liberatore [25], Hermann [26], and Shmatikov [27] classifiers cannot distinguish Castle traffic from regular game traffic with success much better than random guessing.

Together, these results show that video games offer promise as a target for covert channel development and that video games may enable circumvention tool developers to gain the upper hand in the arms race against censors.

**Paper outline.** In Section 2, we present the adversary model that we consider in this paper. Section 3 provides some background on real-time strategy games, details the properties that makes them favorable for use as cover protocols in covert channels, and explains how Castle makes use of each of these for sending and receiving covert data. In Section 4, we provide details on our publicly available implementation of Castle. Following this, we describe our evaluation framework in Section 5. In Sections 6 and 7, we present the results of Castle’s security and performance evaluation, respectively. In Section 8, we discuss the impact that Castle makes on the currently ongoing censor-developer arms race, modifications that may be made to Castle for additional throughput gains, and compare the primary design principles of Castle with it’s most similar counterparts. Finally, in Section 9, we draw our conclusions and provide a link to a video demonstration of Castle.

## 2. Adversary and Threat Model

In this paper, we consider a network-level censor (e.g., an ISP) who is able to perform analysis over all traffic that it forwards from or to clients within its network. It may also perform manipulations (e.g., dropping packets, injecting packets) of the network traffic via on-path or in-path middleboxes. The adversary may also take an active approach and probe application endpoints or otherwise interact with the game.

In this section, we overview the capabilities of the censor that we aim to evade using Castle. We describe the resilience of Castle to these adversary behaviors in Section 6.

### 2.1 Network traffic attacks

**Passive analysis.** We consider censors that are able to perform stateless and stateful passive analysis of traffic at line rate. In particular, the censor is able to perform the following passive analyses to detect the use of a circumvention tool:

- **IP and port filtering:** The censor can observe the IP addresses and port numbers of connections on their network (e.g., using standard tools like Netflow [28]).
- **Deep-packet inspection:** The censor may look for specific patterns in packet headers and payloads (e.g., application payloads indicative of a specific game).
- **Flow-level analysis:** The censor may perform statistical analyses of flow-level characteristics such as inter-packet times and packet sizes.

The first two of these capabilities mean that the ISP can easily detect flows related to the video game in general. For example, if the game uses a specific set of servers (IPs) or ports these flows may be easily identified. Similarly, game-specific application payloads can reveal game traffic to the ISP. The last property can reveal information about game behavior to the ISP (e.g., rate of play). A circumvention system must avoid perturbing these features to remain undetected and unblocked.

**Active manipulations.** In order to detect and/or disrupt the use of censorship circumvention tools, censors may perform a variety of active manipulations on suspicious connections that transit its network. In particular, the censor may drop, insert, or delay packets. Additionally, they may also modify the packet contents and headers. The adversary may perform these manipulations to observe the behavior of flow endpoints to distinguish legitimate game traffic from the covert channel. They may also use these actions to block covert connections (e.g., sending TCP RST packets, or dropping traffic).

### 2.2 Application layer attacks

In the context of detecting look-like-something covert channels, censors may take additional actions outside the scope of standard active and passive analysis. Specifically, they may interact with the application that the covert channel aims to hide within. They may join game servers and observe games in progress (i.e., who is playing with whom). They may observe properties of the games (e.g., map state, player move behaviors) or join and interact with game players if the game is not password protected.

**Censor limitations.** We impose some limitations on the computational capabilities of censors. While they have a large amount of computational resources, they are still unable to decrypt encrypted communication channels and guess high entropy passwords. We also assume that the censor does not have a back door into the game or game servers. For example, we assume the censor is not able to break into the game servers (e.g., by exploiting a buffer overflow or other bug). We also assume that the operators of the game servers do not cooperate with the censor, e.g. they do not allow the censor to see other user’s private game state.

## 3. The Castle Circumvention Scheme

Castle aims to demonstrate that secure and low-bandwidth look-like-something defenses are possible via interactive channels such as real-time strategy video-games. In this section, we provide a background on real-time strategy games and highlight key properties of these games that enable Castle to create covert channels that generalize to the entire genre. We then describe how Castle encodes, sends, and receives data.

### 3.1 Real-time strategy games

Real-time strategy games are a genre of video games that center around the idea of empire-building. Typically, the goal is for a player to assert control over enemy territory through a combination of military conquest and economic maneuvering. Below we highlight commands and features that are common to a large majority of real-time strategy games (Table 1).

- **Units:** Real-time strategy games allow players to create and train a large number of units (e.g., human characters, livestock, machinery). Units may perform many actions e.g., in 17 of the Top 20 best-selling real-time strategy games, a unit can be instructed to move to a location on the map by left-clicking it and then right-clicking the destination location on the map.
- **Buildings:** Players may construct a number of buildings over the course of a game. Buildings are required to train
certain units and research new technologies. For instance, barracks may be required to train infantry. Some buildings produce new units of other types. In most real-time strategy games, unit-producing buildings can be assigned a rally point – i.e., a location on the map at which all units created by the building will assemble. This command is available in 17 of the Top 20 best-selling real-time strategy games.

- **Maps and map editors**: Real-time strategy games are set in a landscape covered by plains, forests, mountains, and/or oceans. Most real-time strategy games allow users to create their own maps and modify existing maps for use within the game. Map editors released by the publisher or the modding community are available for 17 of the Top 20 real-time strategy games.

- **Replay files**: Players may be given the option to record all moves and commands issued by themselves and other players in the game. This is used to replay or watch previously played video-games. When this option is enabled, the game writes, in real-time, all commands issued in the game to a replay log that may be in a proprietary format. Replay file decoders are available for 11 of the Top 20 real-time strategy games.

In addition to the above elements, many commercial real-time strategy games also possess the following networking and security properties that are advantageous for use as cover protocols for covert channels.

**Network communications.** For scalability reasons, real-time strategy games do not broadcast state information to all players in the game. Instead, they pass commands issued by the players in fixed intervals (e.g., 100 ms). These commands are then simultaneously simulated in each game client. This allows clients to execute the game identically, while requiring little bandwidth [29]. As a consequence, any data encoded as an in-game command is received as such, by players at the other end.

Additionally, while most real-time strategy games make use of UDP channels for command communication, reliability is implemented in the application layer. This makes many active traffic manipulation attacks described in previous work [19] ineffective.

In terms of network architecture, real-time strategy games may take two forms, with players joining a common game hosted on a game server (e.g., servers hosted by game publishers such as Microsoft, Blizzard, Electronic Arts, etc.), or connecting directly to each other in a peer-to-peer mode. Therefore, any covert channel system utilizing video games as a cover, can employ whichever is the dominant mode of operation and shift from one to the other if required, to evade censorship.

**Security considerations.** Real-time strategy games often implement several security mechanisms in order to prevent cheating in multi-player game sessions. These include encrypting and authenticating the communication channel that carries player commands, verifying the consistency of the game state with other clients in the game, and restricting access to game sessions via a password.

These security mechanisms have several vital consequences for their use as covert channels. First, since the game command channel is encrypted, passive adversaries are unable to view commands issued by players in a game by simply observing network traffic. Second, the presence of authenticated channels and game-state verification algorithms prevents active attackers from using falsified game packets to interact with, or observe other clients on the game servers.

**Commonalities between real-time strategy games.** Our prototype, Castle, leverages the common command structure, map design capabilities, and tools for decoding saved games and replays generated by real-time strategy games. A survey of real-time strategy games reveals that 11 of the top 20 best-selling games of all-time also include these features (Table 1).

### 3.2 Building game-based covert channels

**Straw-man approach.** One may consider establishing covert communication channels via the in-game voice and text chat channels. However, this approach has several drawbacks. First, previous work shows that encoded data is easily distinguishable from human audio communication [18, 19]. Furthermore, voice communication channels are fairly uncommon in the real-time strategy game genre. Second, while game data is encrypted, it is often the case that text communication channels are left unencrypted. Finally, while one may expect a fairly constant stream of human issued in-game commands in a real-time strategy game, it is rare to have long text or audio communication while playing the game. These factors allow covert channels built on these approaches to be either difficult to implement and extend, or to be trivially detected by an adversary, or both.

**The Castle approach.** In order to create a covert channel mechanism that is general to the majority of games in the real-time strategy genre, Castle exploits two key properties.

- Most real-time strategy games share a common set of actions. Specifically, the ability to select buildings and assign a location where units created/trained in a building should go. This location is called a “rally point,” and we denote the command of setting the rally point for units created in a given building by SET-RALLY-POINT. Games also provide the ability to move a selected unit to a given location (denoted by the MOVE command). Thus, any encoding that translates data into a combination of unit/building selections and these primitives will be general across most games in this class.

- Most real-time strategy games provide a replay option which saves every players’ moves to disk (for later playback). Therefore, all in-game commands are written to disk where they can easily be read and decoded in real-time.

Castle consists of two main components to send and receive data. These are illustrated in Figure 2. Sending is done by encoding data into game commands and then executing them within the game using desktop automation. The receiving process monitors the log of game commands and decodes this list to retrieve data sent via the system.

Figure 3 overviews how the Castle system could be used to relay data from outside of a censored region to a client within
3.3 Encoding data into game commands

Castle relies on the ability of the player to select units and buildings and set rally points to encode data. A naive encoding may consider selecting each unit and directing it to a different point on the game map to encode a few bytes of information per unit. However, in preliminary experiments, we observed that this approach resulted in a covert channel that could not match the properties of the original game traffic (moving O(100$s$) of units to distinct locations is not a usual action for players).

Encoding in Castle is accomplished, without inflating the amount of game data transferred, using the following scheme. First, the participants in Castle download a custom map (distributed via game forums or stores such as Steam) which contains either $n$ immobilized units (e.g., units placed in unit sized islands, within walls, etc.) or $n$ unit producing buildings (e.g., barracks, stable, etc.). The Castle sending process then encodes data by selecting a subset of these $n$ units and executing either a MOVE command in the case of units or SET–RALLY–POINT in the case of buildings. While we discuss the encoding in the context of units and the MOVE command, Castle is easily implemented using either primitive.

Instead of using selection of each unit to represent a single bit sequence, which would result in $\log_2(n)$ bits of data transferred per command, we use a combinatorial scheme where we select $k$ of the $n$ units, to increase efficiency. Intuitively, the selection of $k$ of $n$ units results in $\binom{n}{k}$ different values or $\log_2 \binom{n}{k}$ bits that may be transferred per command. We use combinatorial number systems [31] to convert $\log_2 \binom{n}{k}$ bits of data into a selection of $k$ of the $n$ units on the game screen. In preliminary experiments, we found that the selection of a constant number of units per command resulted in traffic which was more uniform than regular game traffic. As a result, we adjusted our scheme to select between 0 and $k$ units for encoding to increase variability of packet sizes. Section 6 provides a more in-depth view of how we evaluate our similarity to actual game traffic.

In addition to selecting the set of units, we can also select a location for all $k$ selected units to move to. Note that since we select a single location for $k$ units (instead of $k$ distinct locations) this does not impact the data transfer size. Given a game map with $m = x_{\text{max}} \times y_{\text{max}}$ potential locations we can additionally encode $\log_2 m$ additional bits of data in a given turn.

Assuming a map with $n$ units/buildings, a maximum of $m = x_{\text{max}} \times y_{\text{max}}$ map locations, and a game which allows for a maximum of $k$ units/buildings to be selected simultaneously, the game-independent encoding of covert data into a MOVE or SET–RALLY–POINT command is done as shown in Algorithm 1.

Algorithm 1 Algorithm for encoding covert data into game commands

```plaintext
function ENCODE(data, $k$, $n$, $m$, $x_{\text{max}}$)
  $r \leftarrow \{1, \ldots, k\}$
  $z_1 \leftarrow \text{READ}(data, \log_2 (r))$
  for $i = n$ to 0 do
    if $(i) \leq z_1$ then
      $z_1 \leftarrow z_1 - \binom{i}{r}$
      selected $\leftarrow$ selected $|| i$
    end if
  end for
  $z_2 \leftarrow \text{READ}(data, \log_2 m)$
  $(x, y) \leftarrow (z_2 \mod x_{\text{max} \times \lceil z_2/x_{\text{max}} \rceil})$
  return $\{\text{selected}, (x, y)\}$
end function
```

The combination of selecting between 0 and $k$ units and setting the location to move to, results in an average of

$$\frac{\sum_{i=1}^{k} \log_2 (r)}{k} + \log_2 m$$

bits transferred per command.

As mentioned earlier, one may achieve higher data-rates by always selecting $k$ units, however, this causes identically sized commands and thus affects the packet size distribution.

3.4 Sending covert data

Once the covert data is encoded into in-game commands, the sending process must actually execute the commands in order to communicate them to the receiver. One way to do this is to modify the game AI to issue commands as dictated by our encoder. However, this is non-trivial since most games are closed-source and viewing/modifying game code is not always
Section 3.5 Receiving covert data

Since the receiving game client does not have the same in-game screen as the sending client (due to each client having their camera focused on different map locations), directly observing the commands made by the sending client via the screen output is prohibitively complex. Fortunately, most real-time strategy games maintain a real-time log of all commands issued in the game to enable replaying moves or saving game state. In Castle, the receiving process constantly monitors this log file for commands issued by other participants. These commands can then be decoded back into their original covert data via the decoding algorithm specified in Algorithm 2.

Algorithm 2 Algorithm for obtaining covert data from game commands

```python
function DECODE(selected, (x, y))
    size ← |selected|, z1 = 0
    selected ← SORT-DESCENDING(selected)
    for i ∈ selected do
        z1 ← z1 + (size i−1)
    end for
    z2 ← (y × xmax) + x
    return (base2(z1)||base2(z2))
end function
```

This approach suffers from one minor drawback: replay logs for games from commercial studios are often stored in proprietary and undocumented formats that vary from game to game. However, reverse engineering the format of the replay logs is made significantly easier since Castle only issues MOVE or SET-\text{RALLY-POINT} commands. Therefore, we only need to understand how these commands are stored in replay logs. This can be done by simple techniques – e.g., sending a unit to the exact same location multiple times to allow us to obtain the bytes used to denote the $(x, y)$ destination co-ordinates, etc. Further, for many popular real-time strategy games, these formats have already been reverse-engineered by the gaming/hacking community.

4. Castle Prototype Implementation

In this section, we describe our prototype implementation of Castle. We prototype on two games to illustrate the extensibility of our approach.

- **0 A.D.:** An award-winning, free, open-source, and cross-platform real-time strategy game made available under the GPLv2+ license, by Wildfire Games.
- **Aeons:** A best-selling (currently in the top 5 grossing real-time strategy games of all-time), closed-source, Windows-based real-time strategy game.

Our prototype comprises of ∼500 LOC and was coded in a combination of Python and AutoHotkey (desktop automation) scripts. It includes the following components:

- **Custom map:** To test Castle, we created a custom game map for each of the two games. The map was comprised of $n$ buildings packed as tightly as possible to facilitate our selection-based encoding. For 0 A.D., we created a map with $n = 1600$ buildings on a single game screen, while for Aeons, we were only able to have $n = 435$ (owing to larger unit sizes). For both games, a region large enough to contain 16 bits of location data was left unoccupied. This is used to assign rally-point coordinates to the selected buildings.

Since 0 A.D. stores maps in a simple and readable XML format, the process of map creation was easily automated (via a Python script). This was not the case for Aeons which required manual generation of the map using the official GUI map editor. We are currently exploring automation options for map creation in Aeons.

- **Data encoding and decoding:** Code for translating between covert data and in-game commands (and vice-versa) was written in under 200 lines of Python using the encoding and decoding described in Section 3.3. The output of the encoding code was a vector of buildings to be selected and a single $(x, y)$ coordinate.

- **Desktop automation:** We used the open-source desktop automation tool, AutoHotkey, to execute the series of commands determined by the encoding scheme. Since the locations of all buildings and units were known, selecting and commanding those indicated by the encoding was straightforward.

- **Reading recorded game data:** We implemented code that monitored the log file of commands issued (maintained by the game), for both games. For 0 A.D., this information was already made available in a simple to parse text file. In order to obtain this information for Aeons, the game replay file was parsed using tools made available by the gaming/hacking community. The file was then scanned to obtain each command as a vector of selected buildings and an $(x, y)$ coordinate. The commands were then decoded to retrieve the originally encoded covert data.

- **Coordinate calibration:** The isometric perspective of the game screen posed a challenge during the decoding process. Specifically, the presence of a viewing angle meant that a sender may have intended to move a unit to the screen coordinate $(x_1, y_1)$.
5. Evaluation Setup

We evaluate Castle along two axes. First, in Section 6 we consider security of the Castle by quantifying its resilience to the censor-adversary described in Section 2 and its ability to avoid the mismatches highlighted by Geddes et al. [19]. We then study throughput of Castle using the encoding scheme as laid out in Section 3. We also consider the effect of minor game-specific improvements to Castle’s throughput.

For the evaluation in Sections 6 and 7, we use our implementation of Castle with a building-based map, using SET-RALLY-POINT commands. The evaluation was performed on Windows 8.1 running AutoHotkey [32] for automation. The game was set up in direct connect mode—i.e., the two players were connected directly to each other via their IP address (rather than through the game lobby). Since both players were on the same (fast) university network, negligible effects of lag were experienced.

Castle was used to transfer a randomly generated (via /dev/urandom) 100KB binary file from one player to another. Network traffic generated by the game was captured using Rawcap (a command-line raw socket packet sniffer for Windows) with additional processing done using tcpdump on Linux.

We considered the impact of command rate (i.e., how long AutoHotkey waits between each command) and the impact of the maximum number of buildings selected ($k$) on the performance and security of Castle. For this we varied the command delays from 100 ms/command to 1000 ms/command. In the same vein, the number of selected buildings is varied from 25 to 200. Additionally, to observe the impact of game-specific modifications, we evaluated the throughput of Castle over the closed-source Aëons, with and without any game-specific modifications, in the same settings described above.

In order to compare the traffic characteristics of Castle with characteristics of the standard game, we gathered network traces of regular 0 A.D. two-player games. These were also collected in a similar setting—i.e., with both players on the same university network and via direct connect. Ten traces were collected (one per game played). Each of the recorded games was between 20 and 60 minutes long.

We now perform an evaluation of Castle against the network adversary described in Section 2.

6.1 Resilience to network traffic attacks

**Passive analysis.** We first consider attackers with the ability to perform IP and port filtering, deep-packet inspection, and simple flow-level statistical analysis at line rate.

**IP and port filtering:** Since Castle actually uses an off-the-shelf implementation of the game application, the IP address and ports used by Castle are identical to that of the standard use of the game. This means that an adversary that triggers blocking based on the destination IP (e.g., the game server) or port number, will be forced to block all traffic to and from the game being used as the cover protocol.

In the event that the censor is willing to block all connections to dedicated game servers (often hosted by game publishers—e.g., Electronic Arts, Microsoft, Blizzard, etc.), clients may still utilize Castle in direct-connect mode, forcing the censor into a game of whack-a-mole with Castle proxies hosted outside their jurisdiction. Furthermore, users may also easily migrate Castle to another real-time strategy game whose game servers are unblocked.

It is also worth noting that blocking game flows is not without costs to the censor, specifically with respect to political good will and PR internationally. For example, blocking all traffic for a given game, especially a popular game, may upset citizens within their country and reflect poorly on Internet freedom within the censoring country [33–35].

**Deep-packet inspection:** When used with games that encrypt their communications, Castle is resistant to deep-packet inspection, since the censor cannot decrypt the stream of moves being made.

However, since Castle works by issuing only generic commands (e.g., MOVE and SET-RALLY-POINT), it can easily be detected by DPI boxes if the game communicates commands in plain-text. Fortunately, most commercial real-time strategy games perform command channel encryption (e.g., all of the Top 10 best-selling real-time strategy games), making them resilient to such censors.

**Flow-level statistical analysis:** To quantify the resilience of Castle against flow-level attacks, several statistical tests and classifiers were employed. For each experiment, the Castle configuration parameters that control the command rate and the
maximum number of buildings selected in a command were varied between 0-1000 ms and 25-200 buildings, respectively.

First, the Kolmogorov-Smirnov (KS) statistic was used to compare the similarity of human-game-generated traffic and Castle-generated traffic. Figure 4 reflects the KS similarity statistic on the packet size distributions of human- and Castle-generated games and Figure 5 does the same for inter-packet times. We make two observations from these plots: (1) There is a high variation in the flow-level features of legitimate (i.e., human-game-generated) traffic. We hypothesize that this is because the traffic generated by the real-time strategy game is strongly dependent on many parameters such as map and scenario type, strategies employed, and number of players. (2) Castle in many configurations, generates traffic that is well within this variance. We find that while restricting the maximum number of units per command to under 50 and the command rate to around 1 command/second, Castle generates traffic that is as similar to traffic generated by legitimate games.

Next, Castle was evaluated against several website and traffic fingerprinting classifiers. The goal was to evaluate the accuracy of classifiers, built for flow-level analysis, in distinguishing between Castle-generated and human-generated traffic.

First, each network capture was split into (20) one minute long chunks. For each experiment, classifiers were given 20 chunks of Castle-generated traffic at a specific configuration and 20 randomly selected human-game-generated chunks. Ten-fold cross validation was employed for splitting chunks into training and testing sets.

Since, in our experiments, Castle was used for the purpose of file transfer, all traffic generated by it was in a single direction. This makes it trivially detectable by some fingerprinting classifiers which are heavily reliant on burst and direction features (e.g., k-NN [36], the Panchenko classifier [37] and OSAD [38]). We note that in a real deployment this directionality would not be an issue as there would be requests/responses from both sides.

Due to the directionality of traffic, website fingerprinting classifiers that ignored directional information were used. These included the Liberatore classifier [25], the Herrmann classifier [26], and an inter-packet timing classifier [27]. All classifier implementations were obtained from Wang’s open-source classifier archive [39]. The results of these experiments are illustrated in Figure 6. In general, the results indicate that Castle performs very well against packet size and timing classifiers, with only the Herrmann classifier achieving an accuracy of over 60% against multiple configurations of Castle. This is not much better than random guessing.

Active traffic manipulations. In the face of active traffic manipulation attacks, such as probing, packet injection, and modification, Castle implemented over most commercial games faces little threat.

Packet injection. If Castle is implemented over a real-time strategy game with an encrypted and authenticated command channel (e.g., any of the Top 10 best-sellers of all time), any packets injected by an unauthenticated source are dropped by the game-server. As a result, a probing adversary learns nothing about the Castle games running on the server.

Packet modifications. Most packet modification attacks are prevented by the presence of encrypted and authenticated in-game channels. Additionally, since Castle does not require any changes to the game or the hosting server, such attacks will always elicit the same response from both, legitimate game players and Castle users.

Packet dropping and delaying. Although most commercial real-time strategy games make use of UDP as a transport, the presence of reliability implemented in the application layer prevents any threats from adversaries that drop, or significantly delay packets in transmission. As a result, attacks (e.g., [19]) that result in denial-of-service for Castle users are not possible
without also affecting legitimate game players.

6.2 Resilience to application layer attacks

Highly motivated censors may perform actions outside the realm of standard network traffic analysis and manipulation. We consider censors that may interact with the game server using custom game clients in order to reveal the identities of Castle users. Specifically, censors may connect to game server channels and in peer-to-peer mode in direct-connect multi-player games, Castle proxies may host games using high-entropy passwords distributed using, for example, a BridgeDB-like mechanism [40]. Therefore censors without knowledge of the password are unable to join Castle games and learn the IP addresses of Castle clients.

If the cover does not support the use of password-protected multi-player games, Castle proxies may host games using high-entropy passwords distributed using, for example, a BridgeDB-like mechanism [40]. Therefore censors without knowledge of the password are unable to join Castle games and learn the IP addresses of Castle clients.

6.3 Avoiding covert channel pitfalls

Geddes et al. highlight three key mismatches between covert channels and cover traffic which make these look-like-something circumvention tools detectable to external observers [19]. Here we discuss how Castle avoids each of these three mismatches.

The architecture mismatch. Games provide agility in terms of architecture that few other channels provide. They often operate in client-server mode on publisher-hosted game servers and in peer-to-peer mode in direct-connect multi-player games. Our proxying approach can operate in whichever mode is the dominant, and in the presence of blocking can even shift (e.g., from client-server to peer-to-peer).

The channel mismatch. While game data is typically communicated over a UDP channel, it is not resilient to packet loss like other UDP-based channels (e.g., VoIP), thus clients come ing the unit corresponding to the byte to be encoded.

We then sequentially transfer the data byte-by-byte via select-

7. Performance Evaluation

Without any game-specific modifications, Castle offers performance amenable to transfer of textual data (e.g., tweets, e-mail, news articles).

Since each real-time strategy game has a limit on the number of objects that can be selected for a single command, the data rate obtained by Castle is game dependent. For example, 0 A.D. allows the selection of up to 200 units for a single command, giving us an average of \( \frac{2^{20} \log_{2} (1000)}{200 \times 8} \approx 65 \text{ bytes per command.} \)

On the other hand, Aeons has no limits on the number of units that may be selected for a single command but allows only \( \leq 435 \) objects to be placed within a single screen – giving us an average of \( \approx 39 \text{ bytes per command.} \)

Throughput is also dependent on the time required by the desktop automation tool to perform the actions required to issue a command (i.e., click each unit to be selected and click the target coordinate). We found that on average, issuing a single command required between 300-350 ms. With no delays between the issue of each command, this allows \( \approx 3 \text{ commands/second.} \)

In Figure 7, we see the effect of Castle’s parameters on its performance when implemented over 0 A.D. Specifically, Figure 7a shows the effect of increasing the maximum number of buildings selected in a single command and Figure 7b demonstrates the effect of decreasing the command rate. At a configuration where Castle may select up to 200 buildings in a single command and issues commands with no delays in between, Castle implemented over 0 A.D. is able to provide a data rate of \( \approx 190 \text{ Bytes per second} \) – requiring about 52 seconds for the transfer of a short 10KB text news article.

7.1 Game-specific enhancements for Castle

In this section, we show that the performance of Castle can be improved significantly through simple game-specific tweaks. To be able to observe the impact of these game-specific modifications, Aeons was used as the channel for vanilla Castle and Castle with Aeons-specific modifications. The game-specific modifications were introduced and implemented for Castle in just under three hours by an undergraduate researcher.

The low throughput of Castle over Aeons was because Aeons had larger units than 0 A.D., thereby allowing players to place only 435 units within a single screen (as opposed to 1,600 for 0 A.D.). As a result, the throughput of vanilla Castle was only \( \approx 38 \text{ bytes/command (i.e., } \leq 130 \text{ bytes/second)} \) at best – i.e., with the maximum command rate of AutoHotkey and selection of up to 435 units/command.

A quick investigation into the Aeons replay mode and save-game files revealed that even the selection of a single unit was communicated over the network and logged by other players. We exploit this fact by creating a set of \( 2^m \) units (256 in our case) and mapping each unit to an \( m \)-bit value (i.e., a byte). We then sequentially transfer the data byte-by-byte via selecting the unit corresponding to the byte to be encoded.

The success of the voices feeds [41] during the Arab Spring shows that in some situations textual data is enough to get information out.
This encoding allowed AutoHotkey to issue commands at a significantly faster rate than before (a command was now just a single mouse click, as opposed to up to 435 key presses and clicks). At AutoHotkey’s fastest mouse click rate and \( m = 8 \), this encoding achieved a throughput of up to 3KByte/second. However, in order to more closely mimic the command rate and traffic generated by a human player, we add a delay of between 2 and 3 ms per command. In Figure 8, we show the effect of this game-specific modification on the throughput of Castle. From the same figure, we can also observe the effect of varying the total number of units with vanilla Castle and the Aeons-specific version of Castle. We see that increasing \( n \) results in a linearly increasing throughput for vanilla Castle, and a logarithmically increasing throughput for Aeons-specific Castle. However, because the cross-over point of these functions is higher than the game allows, Aeons-specific Castle always achieves better throughput for Aeons.

8. Discussion

In this section, we discuss Castle in the context of its ability to provide deniability to users of the system and provide extensibility that can tip the scales in favor of circumvention developers. We also discuss various methods to improve the throughput of Castle and compare the design methodology of Castle with the most similar related work – Rook and FreeWave.

Deniability and ease of distribution. One of the advantages of Castle is that the covert channel is largely implemented with off-the-shelf software components with only a few hundred lines of code dedicated to encoding data and desktop automation scripting. Desktop automation tools, are already commonly used by gamers and the game, game-specific mods, etc., are generally widespread enough to warrant little suspicion from censors (e.g., Aeons is installed by millions of users). Castle’s small core size also makes it easy to distribute through hard to block methods – e.g., via the text body in emails and even through instant messaging services.

Extensibility of Castle. Castle’s strength comes from the ease with which it can be ported to new games. As an example, it took a bright undergrad less than 6 hours to complete a basic port of Castle over a very popular closed-source real-time strategy game. Due to the availability of game-specific hacks and reverse engineering guides in popular gaming forums [42–44], completing game-specific enhancements in order to improve the data rate of Castle, as described in Section 7.1, required only an additional 3 hours.

Although individual game titles do not present a high collateral damage, in the event that they are blocked, Castle presents a simple way to convert each of them into an ephemeral and effective covert channel, with little development overhead. This ability, along with the fact that every newly released title is a potential covert channel, makes Castle particularly useful in the arms-race that censors and developers are currently engaged in. In particular, it is the first censorship circumvention tool to provide an asymmetry in favor of the developer (i.e., creating a new channel is significantly less expensive than detecting the channel).

Improving Castle throughput. In addition to making game-specific modifications, Castle presents many opportunities to increase throughput of the system.

- **Parallel requests.** Since most modern real-time strategy games allow up to eight players to participate in a single multi-player game, it is possible for one censored user to decode content responses from up to seven proxies in parallel – achieving up to 7x downstream throughput. This is particularly useful in the context of web data, where requests are easy to parallelize.

- **Content compression.** Castle proxies may improve performance by compressing requested content before encoding. In the context of web data, the proxies may also pre-render and compress content before sending them to the receiver (e.g., as was done by the Opera mobile browser [45]).

- **Trade-off throughput and detectability.** Depending on the level of surveillance in a given region Castle may expose an option to allow users to trade off throughput vs. detectability of the system (e.g., by increasing the rate of clicks in the automation tool).

Comparison of design methodology. In terms of design
methodology, Rook and FreeWave are most similar to Castle. Like Castle, Rook also uses games as the cover protocol, although the goals of Rook and Castle are quite different. The primary goal of Castle is adaptability – Castle is loosely coupled to the underlying game, enabling developers to quickly adapt Castle to many games. Rook is focused on steganographic security; even if the adversary is able to join the same gaming session as two Rook users, the attacker will still not be able to determine whether the other players are using Rook to surreptitiously transmit data. As a result, Rook aims for security against a very powerful adversary, but has over 100x lower bandwidth than Castle.

FreeWave and Castle are similar in that they both work above the application layer, mimicking user input to the application, rather than the application itself (FreeWave uses a modem to encode data into audio transmissions over VoIP clients). Similar to Castle, FreeWave also allows extensibility to other similar applications. However, there are significantly more real-time strategy games available for use as cover protocols than there are VoIP clients.

To the best of our knowledge, Castle is the only covert channel that (1) appears to satisfy all the covert channel design principles laid out by Geddes, et al [19], (2) provides extensibility to hundreds of applications (games), potentially with only a few hours effort for each, and (3) is evaluated for security at the application and network layer.

9. Conclusions

In this paper we have presented Castle, a general approach for creating covert channels using real-time strategy games as a cover for covert communications. We demonstrate our approach by prototyping on two different games with minimal additional development overhead and show its resilience to a network adversary. We argue that the popularity, availability, and generic functionalities of modern games make them an effective circumvention tool in the arms-race against censors. Specifically, our results show that Castle is:

- **Secure**: Castle is resistant to attacks such as IP/port filtering and deep-packet inspection since it actually executes the game application. More complicated and expensive attacks such as traffic analysis attacks are avoided due to the high variability of standard game flows.

- **Usable**: Even without any game-specific modifications, Castle is able to provide throughput sufficient for transfer of textual data. Additional enhancements make it suitable for use as a web proxy.

- **Extensible**: Incorporating new closed-source games as covert channels for Castle requires only a few hours of developer time – including the addition of title-specific enhancements for increased throughput.

The results presented in this work motivate two independent future research directions. First, extending our work to different classes of games which may enable higher throughput rates (e.g., racing games, first person shooters). Second, integrating the Castle approach into platforms to make it usable to users e.g., via a Web browser plugin or integration with the suite of Tor Pluggable Transports [15].

**Code and data release**: To ensure reproducibility of our results and ease comparative evaluation, our implementation of Castle is available at https://github.com/bridgar/Castle-Cover-Covert-Channel.

**Video demonstration**: A video demonstration of Castle implemented over 0 A.D. is available at https://www.youtube.com/watch?v=zpjZJuYWmDE.
